Abstract: Our recent results on the demonstration of on-chip mode-division multiplexing functionalities are reviewed, with a special emphasis on the feasibility of nonlinear all-optical signal processing on the silicon-on-insulator (SOI) platform. Mode-selective parametric processes are demonstrated in a 4-mm long SOI waveguide.

OCIS codes: (130.3120) Integrated optics devices; (030.4070) Modes; (130.7405) Wavelength conversion devices; (190.4380) Nonlinear optics, four-wave mixing; (060.4230) Multiplexing; (200.4650) Optical interconnects.

1. Introduction

Space division multiplexing (SDM) has recently established itself as one of the leading technologies that could potentially contribute to avoiding a foreseen "capacity crunch" in a cost effective way in optical fiber telecommunication systems [1]. In particular, mode division multiplexing (MDM) makes use of the spatial modes of few-mode fibers to increase the throughput of optical links while sharing transmission equipment such as optical amplifiers among the modes. Impressive demonstrations with up to 6 spatial modes have been reported [2]. While the focus was initially on demonstrating the feasibility of point-to-point mode-multiplexed transmission, networking considerations are now also the object of investigations [3]. Indeed, the introduction of wavelength division multiplexing (WDM) has not only enabled the transmission of massive amounts of data over optical fibers, but has also provided network designers with a degree of freedom, the channel wavelength, that was relatively easy to handle in order to perform operations such as add-drop multiplexing or routing. The situation is fundamentally different for MDM transmission over optical fibers, where the use of multiple-input multiple-output (MIMO) digital signal processing following coherent detection is often a requirement in order to be able to retrieve the individual mode-multiplexed channels.

Optical transmission systems have become increasingly complex over the years, evolving from simple on-off keying intensity modulation to the use of multilevel modulation formats exploiting the phase dimension, as well as making use of polarization multiplexing. The field of all-optical signal processing had to continuously adapt to this evolution in order to design processing schemes (such as wavelength conversion, switching, regeneration etc.) that are compatible with those new requirements imposed by the introduction of new transmission technologies. It is therefore essential to study the feasibility of new optical signal-processing techniques that are compatible with MDM and can take the form of mode-independent or mode-selective processing. The developed signal processing toolbox could then contribute to the definition of future network elements. While optical nonlinearities in MDM systems have been studied from the perspective of transmission impairments [4], very little work has been carried out so far on their exploitation for all-optical signal processing. The integration capability, for instance on the silicon photonic platform, will also play a crucial role in view of future commercial implementations.

Another area that could take advantage of MDM is on-chip optical interconnects. Here, the introduction of optical technologies is seen as promising in order to meet the bandwidth demand of multiple-core processor architectures while keeping the power consumption of communication at an acceptable level. Optical networks on chip (ONOCs) are therefore the object of increased attention and a number of architectures, often relying on WDM and the use of wavelength selective components such as micro-ring resonators (MMRs) have been proposed [5]. One current limitation of the WDM approach is the difficulty to integrate light sources on the silicon platform, even though this endeavor is a very active area of research at the present time. The use of MDM could reduce the number of required sources, hence the footprint of the optical layer. Used in conjunction with WDM, MDM could offer new possibilities to route signals on optical chips. Integrated mode-multiplexing and demultiplexing devices have been proposed and demonstrated, and some point-to-point on-chip MDM transmission experiments have been recently performed [6-10]. Signal processing could, once again, enable networking functionalities such as switching, multicasting, etc., provided it can be implemented in a way that is compatible with the wavelength and space (mode) dimensions.

Finally, thanks to their strong confinement that makes it possible to fabricate waveguides that are both multimode and nonlinear at the typical power levels compatible with optical communication systems, high-index contrast waveguides constitute a great platform for experimentation on multimode nonlinear effects.

In this paper, we review some of our recent results on on-chip mode division multiplexing. We first present the building blocks for MDM transmission on a silicon-on-insulator (SOI) chip. We then illustrate the concept of all-optical signal processing for on-chip MDM by reporting mode-selective wavelength conversion in an SOI waveguide.

2. On-chip mode multiplexing

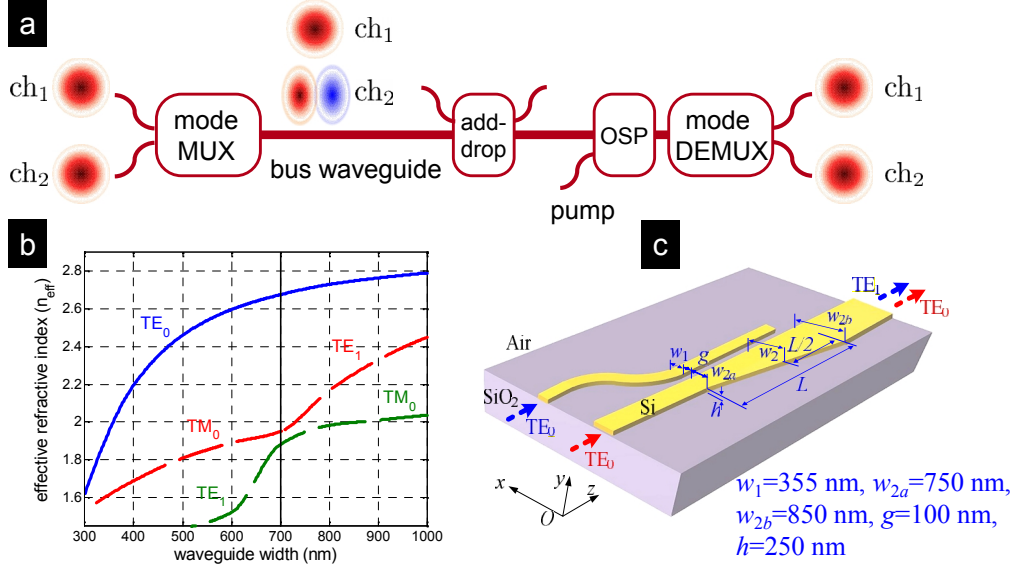

Fig. 1. (a) Principle of an on-chip mode-multiplexed system. (b) Effective indices of the TE_0 , TE_1 and TM_0 modes of an air-clad SOI waveguide of height $h=250$ nm as a function of the waveguide width. (c) Layout of a TE_0 and TE_1 mode (de)multiplexer based on a tapered asymmetric directional coupler.

The principle of on-chip mode multiplexing is illustrated in Fig. 1(a). A multimode bus waveguide is used to simultaneously transmit signals carried by different spatial modes at the same wavelength. This requires mode multiplexing and demultiplexing devices to be designed and fabricated. Along the transmission line, mode add-drop multiplexing can be performed, as well as nonlinear optical signal processing (OSP). WDM can be employed as an extra dimension to further increase the capacity, or as a way to provide a control signal for OSP. A simple asymmetric directional coupler can be used as a mode multiplexer. Fig. 1(b) represents the effective indices of the modes supported in an SOI ridge waveguide with top air cladding as a function of the waveguide width. Waveguide widths can be found so that the effective index of the TE_0 mode in a narrow waveguide matches that of the TE_1 mode in a wide waveguide, thus ensuring a high coupling efficiency between the modes. The use of a taper for the wide waveguide enables to relax the fabrication tolerance of such a mode (de)multiplexer by ensuring proper phase matching occurs at some point along the coupling region. This mode (de)multiplexer structure, represented in Fig. 1(c), has enabled the full system demonstration of a 2-mode multiplexed system at 40 Gbit/s per channel with moderate penalties of 1.6 dB-1.8 dB due to residual crosstalk [8].

3. Mode selective wavelength conversion

Fig. 2. Microscope pictures of the 4-mm long 2-mode SOI waveguide with details of the directional coupler mode (de)multiplexer and the grating coupler used to couple the chip to standard single-mode fibers.

Mode-selective wavelength conversion was realized as an example of all-optical signal processing [11]. A 4-mm long multimode bus waveguide supporting the TE_0 and TE_1 modes and equipped with a pair of mode (de)multiplexers was fabricated, as shown in Fig. 2. Strong four-wave mixing (FWM) occurs when the pump and signal light are on the same spatial mode, while weak FWM is obtained between different modes as a result of phase mismatch. The idler due to inter-mode FWM is suppressed by more than 20 dB compared to the idler resulting from the interaction of pump and signal on the same spatial mode. The converted idler is extracted from the nonlinear waveguide thanks to a mode demultiplexer.

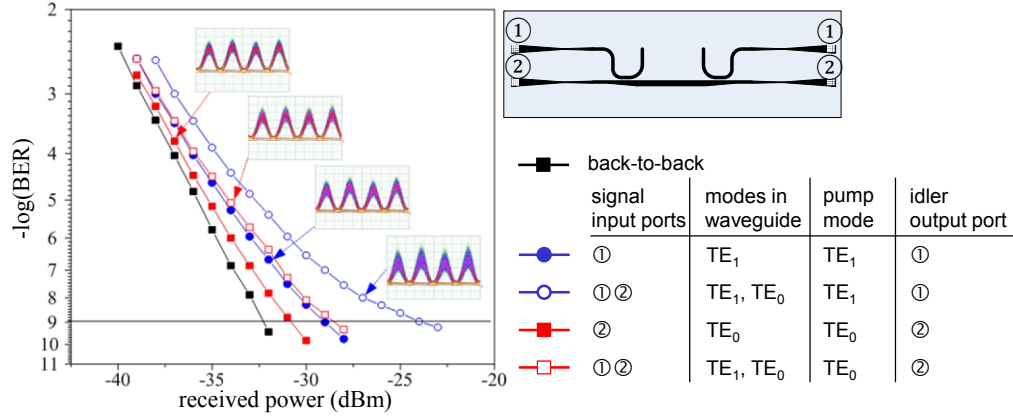

Fig. 3. BER characterization of mode-selective wavelength conversion.

The good selectivity of the process enables its dynamic characterization with modulated signals. The pump light was modulated at 40 Gbit/s in the return-to-zero format while the mode-multiplexed signals were continuous waves. Wavelength converted modulated signals are obtained on one or the other mode depending on the choice of the mode on which the pump wave is coupled. The results of bit-error-ratio (BER) characterizations are reported in Fig. 3, where the influence of the modal crosstalk is assessed. Improvement in multiplexer design and fabrication is expected to allow a reduction of the modal crosstalk.

4. Conclusion

The motivations behind the investigation of on-chip all-optical signal processing have been reviewed. Mode-selective wavelength conversion has been demonstrated at 40 Gbit/s in a silicon-on-insulator waveguide supporting two spatial modes. Other signal processing functionalities are under investigation.
